#### **Abstract**

This paper is describing the preliminary results of the Annex 27 work aiming at developing simplified tools for evaluating domestic ventilation systems. In this paper is given the tool to evaluate a system's ability to deal with different indoor air quality (IAQ) matters. In the work is used sophisticated simulation programs studying pollutant concentration either for each person or in an individual room. The evaluation is to be applied on houses that mainly are heated. This means that the tools are restricted to the heating season.

Assumptions, based on previous research works, are set up for a number of parameters. The total number of combinations are about 17 500 and have been reduced to 174 by statistical methods for multi variant parametric studies and fractional factorial analysis. With this reduction of the number of combinations it is possible to make all the runs even with sophisticated multizone models. The result is presented as coefficients for the various pollutants.

## **Background**

The rate of outdoor air supply as well as comfort aspects associated with air distribution and the ability of the systems to remove pollutants are important factors to be considered at all stages in the building lifecycle. As distinct from a work place, residents can vary across a wide span from an allergic infant to a well trained sportsman, from active outgoing people to elderly confined to a life indoors.

During the lifetime of a building the resident's pattern vary. This results in a varying need for supply air to obtain acceptable indoor climate and to avoid degradation of the fabric. Emissions from building materials are also time dependent. When the building is new or recently refurbished it may be necessary to dilute the emissions by extra outdoor air. In standards and codes the outdoor air needed in a dwelling is generally based on the maximum number of persons living in the dwelling, defined by the possible number of beds contained therein.

Dwellings represent about 25-30% of all energy used in the OECD countries. In the near future domestic ventilation will represent 10% of the total energy use. Thus even

relatively small reductions in overall ventilation levels could represent significant savings in total energy use. Improvement of residential ventilation is of concern in both existing and future buildings. The functioning of the ventilation system may deteriorate at all stages of the building process and during the lifetime of the building. Research in the recent years and in particular the IEA annexes now makes it possible to formulate methods to evaluate domestic ventilation systems. to be the sound of the RA sound of the

an very concurrent the ALIC countries gave, that the nate, frequent certific in system is ather and some singley whatew epening to wever, in new constitutions at moand less a find is installed staber for central a hand or for least extractional materials and/or Euchen.

With the above objectives and scopes of the three subtasks the Annex started in April 1993 and has today eight participants: Canada, France, Italy, Japan, Netherlands, Sweden, UK, and USA. Based on the subtask "State of the Art" assumptions have been set up to develop simplified tools for:

- In order to develor sincel fied took has the index our justicy, a set of a surproces of 1. Indoor Air quality (reported in this paper) dimed behalf of select orall about so of

With the State of the Art Review, ref 1, it is possible to give realistic assumptions of the most frequently used ventilation systems, the design of the dwellings, how many

residents there usually are, the behaviour, and the time spent in dwellings. With these assumptions we can cover about 90% of all possible cases, that are influencing the need of outdoor air supply. The usual levels of different pollutants in the dwellings are also given based on the review. The review report is based on and giving references to about 400 reports.

The 14 OECD countries studied have 700 million inhabitants, 280 million dwellings with a floor space of 32 0000 million m<sup>2</sup>. The habitable space varies greatly and goes from 65 m<sup>2</sup>/dwelling (Italy) to 152m<sup>2</sup>/dwelling (USA). There is also a great variation between the countries how many dwellings there are in single family houses or in multi family buildings.

The number of persons/dwelling goes from 2.1 (Sweden), to 3.2 (Japan, Italy). Combined with the dwelling area it gives a floor space from 27 m²/person (UK) to 61 m²/person (USA). The crowdiness is defined by the number of persons/bedroom. From data can be seen that in 35% - 50% of all dwellings, there is less than 1 person/bedroom and in nearly all (90 - 95%) less than 2 persons/bedroom. Moving frequency studies show, that after 35 years of age the family has settled and will remain living there in that dwelling.

A very important trend is, that the number of one-person household, is increasing. Today it goes from 20% (Japan) to 40% (Sweden). This trend has been observed during the last 45 years in all countries. A majority of the households consist of only two persons, except Japan (40%). In the future it can be expected that the number of 1-and 2-person households will grow as the number of persons older than 60 years during the next 40 years will increase from about 20% today to 30% of the population.

A survey amongst the AIVC countries gave, that the most frequent ventilation system is either stack or simply window opening. However, in new constructions in most countries a fan is installed either for central exhaust or for local extraction in bath and/or kitchen.

with above nejectives one segme of the ibstants. A mox statter in open is and the above of the periodical Chinadia. Whence the stopping Neutralands. The estimates the estimate of the control of the basic standards.

In order to develop simplified tools for the indoor air quality, a set of assumptions had to be made. Here is also included family pattern both for weekdays and weekends. Such assumptions are time schedule at home and in the individual rooms, for taking showers, cooking, smoking, window airing. In table 1 can be found the parameters the simulations are made for. The common way to do parametric studies are to vary one parameter and keep all the others constant. By this you will not get the extreme combinations.

By selecting a representative number of the total combinations out of nearly 17 500, it is possible to make simulations for a statistically representative number of combinations of the parameters, "multi variant parametric study". The combinations of the values of the

parameters are selected by the method "fractional factorial analysis". The number of runs is given by choosing the IVth resolution, see ref 2. Then the regression analysis of the result is giving coefficients, which can be applied on that specific case you are interested in. By this it is possible to give quantitative values and also give rankings between different solutions.

This paper describes the results from the first complete 174 runs made by the semi-multizone program called SIREN developed by CSTB, France, see ref 3. The aim is to do the same with the true multizone program COMIS.

Here follows a short description of some of the assumptions. See also table 1.

Example dwelling: A number of dwellings were assumed, typically for the participating countries. Two type dwellings were selected as the assumed number of persons in each dwelling have the area per person for the crowded case. The dwelling types selected are a 4-room flat either on the ground floor in a 4-storey multifamily building or on the top floor (D4a) and a 4 room detached single family house (D4c).

Ventilation systems: The four main systems are: 1 adventitious or natural window airing (Airing), 2 natural passive stack (Stack or S), 3 mechanical exhaust (Exh), 4 mechanical supply and exhaust (SE). All systems can be combined with local fans.

Family types: Three cases crowded (5 persons), average (4 persons), spacious (2 persons)

Leakage: Three cases are given with more airtight envelope if mechanical supply and exhaust ventilations system is used. Tighter for flats.

Window airing: Assumed to take place only in bedrooms. Three cases are given 1 closed window, 2 opening pattern depending on the outdoor temperature and wind speed, and 3 a medium case with 50% of the opening area depending of the climate.

Clothes washing and drying: Base case with no water vapour.

**Indoor temperature:** + 20°C

**Body washing:** All residents are taking a 10 min shower every day in the morning Tobacco smoking: The woman is smoking in the living room when at home after 13.00h

In table 1 is indicated the level which is purely used when interpreting the combination given by the fractional factorial analysis and here "+1" indicates that the high value is to be used in the calculation, "0" the medium value, and "-1" the lower value. By combining column DWA and DWB the type dwellings are selected to be D4a on ground floor or on top floor in a 4-storey building or detached house D4c. In table 2 is given the number of factors for each parameter and the number of runs for each of the ventilation systems.

#### **Results**

The regression analysis have given a set of coefficients for each of the indoor air quality factor and for each system. Results for supply and exhaust ventilation systems are presented here. The approach is illustrated in table 3.

The results of the complete simulations will give for each case the following indoor air quality and energy parameters.

- 1. Human metabolism. CO<sub>2</sub> concentration above outdoor level. The number of hours the most exposed person is exposed for 700 ppm or 1400 ppm. (Here 1400 ppm is never reached).
- 2. Cooking products, e.g. water vapour, CO, NO<sub>2</sub>. The number of hours.
- 3. Passive smoking. The most exposed person besides the smoker. Number of hours.
- 4. Pressure difference. If the dwelling has a too high or too low pressure difference it might give a risk for radon, combustion spillage, and interstitial condensation. This is indicated if the number of hours are more than 200 h.
- 5. Dryness feeling. The number of hours < 30% RH.
- 6. Condensation. Number of hours of possible condensation in wet rooms on internal walls and for habitable rooms on a 2-pane window. This will indicate the risk for mauld growth and degradation of the building fabric.
- 7. House dust mites. Checking if there is a 4 week period with the water vapour content < 7g/kg all the time. At this value the house dust mites do not grow.
- 8. Outdoor air change rate in the individual habitable rooms and overall for the dwelling.
- 9. Energy both for heating the outdoor air and for the fan energy also taking into account heat recovery possibility.

The pollutant production is assumed to be constant when smoking. The presence in the dwelling varies and is depending on which case that is selected. For the crowded and average cases presence is 41 h/week and for the spacious case only 27 h/week.

This presentation of the results are given as factors for some of the above parameters, see table 3. As the code, SIREN, is a semi-multizone computer code, the result is given for all the habitable rooms together or the most exposed person except smoking. Both additative and multiplicative regression analysis has been tested and the best fitted is selected.

#### **Discussion**

This presentation of some of the pollutants for one ventilation system is indicating the procedure of the work within Annex 27 to predict the indoor air situation for a very large number of combinations. By using simulation technique it is possible to run a statistically selected number of combinations representing a large number of combinations. As it is too expensive to do a simulation run on an individual dwelling

for each case with a number of assumptions, the final aim is to give possibilities to evaluate all ventilation systems in an easy way for a variety of pollutants.

This analysis indicates that a regression based on multiplying or adding factors is a possible way. Runs with the code SIREN, that has a short running time for each combination, will be compared with the true multizone model COMIS. The results will also be compared with detailed measured dwellings in the participating countries.

Usually there is no time or money to make detailed computer simulations for ventilation systems in the residential sector during the design process. The simplified tools make it possible to predict the indoor air quality for a lot of different parameters for many ventilation systems. The tool can be used for proposing systems in new houses or when renovation is proposed. It can also be a tool for a first check if any complaint has been made by the residents.

It must be noted that this is a preliminary version and the final one is still to be worked out. Also sensitivity studies are to be carried out on parameters like wind direction, flow rates.
