(Received 9 May 1983 and in revised form 3 Octoher 1983)

#### Abstract

The paper presents a computational method used to obtain solutions of the buoyancy-driven laminar and turbulent flow and heat transfer in a square cavity with differentially heated side walls. A series of Rayleigh numbers. ranging from $10^{3}$ to $10^{16}$ was studied. Donor-cell differencing is used. and mesh-refinement studies have been performed for all Rayieigh numbers considered. The turbulence model used for Rayleigh numbers greater than $10^{6}$ is a $(k \sim \varepsilon)$ two-equation model of turbuience, that includes gravity $\sim$ density gradient interactions. The results are presented in tabular and graphical form. and as correiations of the Nusseit and Rayleigh numbers. Furthermore, the results for Rayleigh numbers up to $10^{\circ}$ are compared with the benchmark numerical solution of de Vahl Davis.

## NOMENCLATURE

cavity width [m]
gravitational acceleration [ $\mathrm{m} \mathrm{s}^{-2}$ ]
kinetic energy of turbulence per unit mass [ $\mathrm{J} \mathrm{kg}^{-1}$ ]
Nu Nusselt number
Pr Prandtl number
$R a \quad$ Rayleigh number, $\rho^{2} g D^{3} \beta \Delta T \operatorname{Pr} / \mu^{2}$
$S$ source term
$T$ temperature [K]
v. velocity component in the $y$-direction [ $\mathrm{m} \mathrm{s}^{-1}$ ]
velocity component in the $z$-direction [ $\mathrm{m} \mathrm{s}^{-1}$ ]
$y, z \quad$ spatial coordinates [m]
$\bar{y} \equiv$ normalized coordinates.

## 1. INTRODUCTION

The determinittion of buoyancy-driven flow in an enclosed cavity provides a suitable comparison problem for evaluating the performance of numerical methods dealing with viscous flow calculations [1-3]. Furthermore, the above process has many practical applications of which the most widely known is that of double glazing. Other applications include nuclearreactor insulation, ventilation of rooms. soiar-energy collection and crystal growth in liquids. There is an ever increasing amount of research on confined natural convection and refs. [4-10] are typical examples of such work. A recent review of the existing literature is given by Ostrach [11]. Despite all the recent research activity, a central problem that has remained unsoived is the coupling between boundary lavers and core flows. The latter depend on the boundary layer, which. in turn, is influenced by the core. This problem was first identified

[^0]by Ostrach [5] and discussed more fully in refs. [6, 7]. The purpose of this work is to describe a computational procedure for solving the non-linear, coupled differential elliptic equations over the entire flow domain, with no assumptions concerning the core configuration or any other ad hoc simplification for Rayleigh numbers up to $10^{6}$, and with the speculative use of a two-equation turbuience model for higher Rayleigh numbers: and to demonstrate that this can be accomplished without excessive demands on computer time or storage. The presented results are restricted to rectangular cavities of aspect ratio 1 , fluids of Prandtl number 0.71 . and Rayleigh numbers ranging from $10^{3}$ to $10^{16}$. However. the procedure is general and can be easily applied for practical computations in cavities of different aspect ratios, fluids of different Prandtl numbers, three-dimensional (3-D) enclosures or tilted enclosures such as, for example, those studied by Catton [4].

## 2 THE PROBLEM CONSIDERED

The problem considered is depicted schematically in Fig. 1. and refers to the two-dimensional (2-D) flow in a square cavity. of side $D$. The cavity is assumed to be of infinite depth along the $x$-axis and is heated diferentiaily along the South (low-y) and North (high-y) walls. The other two (horizontal) walls are insulated.
The no-slip condition is applied on the velocity at all four walls. and friction is calculated by invoking 'wallfunctions' [12], see Appendix. The hot and cold walls are considered to be isothermal. and the other two adiabatic. Heat transfer through the walls causes density changes to the fluid in the cavity, and leads to buovancy-driven recirculation. The resulting flow is treated as steady and, depending on the Rayleigh number. laminar ( $R a \leqslant 10^{\circ}$ ) or turbulent ( $R a>10^{\circ}$ ). This criterion for switching over to turbulence calculations is based on experimental observations [25, $26]$ and has been used widely in the literature $[1-3,20$,

## CONVECTION TRIDIMENSIONNELIE NATURELLE DANS UN ESPACE ANNULAIRE INCLINE

Résumé-On décris un travail analytique et expénimental sur ia convection naturelle dans un espace annulaire incliné entre un cylindre intérieur chauffé et un cylindre exterieur froid. Les équations tridimensionnelles sont transíomées en des équations aux différences finies et etles sont résolues numériquement en utilisant la méthode de sureiaxations successives (SOR). La structure tridimensionnelle de l"écoulement et les distributions de température et des nombres de Nusselt sont obtenues et l'effer de lïnclinaison est étudié. Une visualisation expérimentale par une technique de traceur est realisée: des photographies confirment la structure tridimensionnelle de l'écoutement obtenue analytiquement.

## DREIDIMENSIONALE NATURLICHE KONVEKTION IN EINEM GENEIGTEN ZYLINDRISCHEN RINGRAUM

Zusammenfassung-Es wird eine theorecische und experimentelle Arbeit beschrieben, die sich mit der natürlichen Konvektion in einern geneigten zylindrischen Ringraum befaßl, wobei der innere Zylinder beheizt und der āubere Zylinder gekühlt ist. Die bestimmenden dreidimensionalen Gleichungen werden in finite Differenzengleichungen transformiert und numerisch gelöst, wobei die sukzessive Uberrelaxationsmethode (SOR) angewandt wird. Dabei werden die dreidimensionale Struktur der Geschwindigkeits- und Temperaturverteilung sowie die Nusselt-Zahlen erhalten, und der Einfluß der Neigung auf diese Größen wird untersucht. Die Strömung wurde mit einem Tracer-Verfahren sichrbar gemacht: Fotografien der Streichilinien bestâtigen die berechnete dreidimensionaie Strömungssuruktur.

## ТРЕХМЕРНАЯ ЕСТЕСТВЕННАЯ КОНВЕКЦИЯ В КОЛЬЦЕВОМ ЗАЗОРЕ МЕЖДУ НАКТОННЫМИ ЦИЛИНДРАМИ

Аннотаиия-Лреבстав.тены резутьтаты анатитического и экспериментатьного исстепования естественной конвекиии в ко.тьиевом $3\{30 р е$ между наклонными нагреваемым внутренним и охтаждиемым внешним цилинבрами. Трехмерные эравнения естественной конвекиии преоо̃разованы в конечно-ризностные и решены численно с использованием метозл верхней релаксации. Получена трехмерная структура раслределений скорости кидкости и температуры. а также опредетены значения чисті Нуссетьта и исследовано влияние на них наклона. Течение в зазоре визуатизировалось с помошью химического индихатора: фотографии штриховых линвй подтвержבают трехмерный характер структуры потока, полученный аналитически.

22]. Reierence fluid properties were calcuiated at the ambient temperature $T_{0}=293 \mathrm{~K}$.

## 3. mathematical formization AND METHOD OF SOLLTION

### 3.1. The differential equations

For steady flow, the equations for continuity, velociry components and temperature take the form: continuity

$$
\begin{equation*}
\frac{\hat{c}(\rho v)}{\hat{c} y}+\frac{\hat{c}(\rho w)}{\hat{c} z}=0: \tag{1}
\end{equation*}
$$

$y$-direction momentum

$$
\begin{equation*}
\frac{\hat{c}}{\hat{c}}=(\rho(x))+\frac{\bar{c}}{\hat{c} y}(\rho r r)=\frac{\bar{c}}{\bar{c}=}\left(\mu \frac{\bar{c} \tau}{\bar{c}=}\right)+\frac{\bar{c}}{\bar{c} y}\left(\mu \frac{\partial v}{\bar{c} y}\right)+S_{\mathrm{r}} \tag{2}
\end{equation*}
$$

$z$-direction momentum
general transported fiuid scalar. $\dot{\phi}(\mathrm{e}$ g. $T, k, \varepsilon)$
$\frac{\tilde{c}}{\hat{c} z}(\rho w \phi)+\frac{\hat{c}}{\hat{c} y}(\rho \tau \phi)=\frac{\tilde{c}}{\hat{c} z}\left(\Gamma_{\bullet} \frac{\bar{c} \phi}{\hat{c} z}\right)+\frac{\tilde{c}}{\hat{c} y}\left(\Gamma_{\varphi} \frac{\hat{c} \phi}{\partial y}\right)+S_{\phi} ;$
where $\Gamma_{0}$ is the exchange coefficient for the transport of property $\phi$. The source terms in the momentum equations are

$$
\begin{align*}
& S_{-}=\frac{\dot{c}}{\dot{c} x}\left(\mu \frac{\bar{c} w}{\dot{c} x}\right)+\frac{\bar{c}}{\hat{c} y}\left(\mu \frac{\bar{c} \tau}{\dot{c} z}\right)-\frac{\bar{c} p}{\bar{c}=}+\rho g \frac{\theta}{T_{0}} ;  \tag{5}\\
& S_{\mathrm{r}}=\frac{\bar{c}}{\hat{c}}\left(\mu \frac{\bar{c} w}{\hat{c} y}\right)+\frac{\hat{c}}{\dot{c} y}\left(\mu \frac{\bar{c} \mathrm{~T}}{\bar{c} y}\right)-\frac{\bar{c} p}{\hat{c} y} ;  \tag{6}\\
& S_{T}=0,
\end{align*}
$$

where $\theta$ is the temperature rise above ambient $T_{0}$.
For Rayieigh numbers above $10^{\circ}$ a two-equation
( $k \sim \varepsilon$ ) turbulence model was used. Then the above equations are time-averaged equations and $\mu$ and $\Gamma_{\phi}$ are replaced by their 'effective' values $\mu_{\text {eff }}$ and $\Gamma_{\text {eff }}$, as given by the turbulence model $[12,13]$.
The generation term in the k-equation includes the buoyancy production

$$
\begin{equation*}
G_{\mathrm{B}}=-\beta g \frac{\mu_{4}}{\sigma_{\mathrm{L}}} \frac{\partial \phi}{\partial y} . \tag{7}
\end{equation*}
$$

In stable stratification, $G_{B}$ becomes a sink term so that the turbulent mixing is reduced. In unstable stratification, the buoyancy will enhance turbulence since $G_{B}$ is positive. The buoyancy term appearing tentatively in the $\varepsilon$-equation, in other $k \sim \varepsilon$ calculations for buoyant hows [14,24], has been omitted. There is no obvious physical reason for including such a term and other related work indicated that it is compietely insignificant [15]. The turbuience model contains five constants which were assigned the following values [12]

$$
\begin{gathered}
C_{1}=1.44 ; \quad C_{2}=1.92 ; \quad C_{H}=0.09 ; \\
\sigma_{k}=1.0 ; \quad \sigma_{\mathrm{E}}=1.314
\end{gathered}
$$

More details may be found in refs. [14, 15].
Assuming that $p$ is proportional to $1 / T$ the densities are obtained from the temperature field. without invoking the Boussinesq-type approximations.

### 3.2. The solution procedure

The above equations were solved on a square mesh by the finite-domain method outlined in refs. [16-18]. Finite-domain equations are derived by integration of the differential equations over an eiementary control volume or cell surrounding a grid node. Upwind differencing is used in the convective terms and the integrated source term is linearized. Both these practices are widely used to enhance numerical stability. The upwind scheme has come under much crivicism recently, but it is only grid-refinement that can detect the 'false diffusion' associated with the various
schemes. Therefore, care was taken to obtain gridindependent results. Pressures are obtained from a pressure-correction equation which yields the pressure change needed to procure veiocity changes to satisfy mass continuity. The SIMPLEST practice [17] is followed for the momentum equations. The most significant difference between SIMPLEST and the well-established 'SIMPLE' algorithm [19] is that in the former the finite-domain coefficients for momenta contain only diffusion contributions, the convection terms being added to the linearized source term of the equations. This implies that, in the absence of diflusion, the momentum equations are solved by a Jacobi point-by-point procedure as opposed to the more popular 'simuitaneous' line-by-line procedures. This mixed practice (the use of Jacobi for convection terms, the use of line-by-line for diffusion terms) derives from experience and intuition. For example, use of Jacobi for diffusion in a pipe would take an extremely long time to spread the viscous effects of the wall, while a simultaneous solution would do that in virtually a single iteration. This is not so for the convection terms, however, because of their special links with the pressure-correction equation. The above mixed practice was found to accelerate convergence significantly.

The equations are solved by a line-by-line procedure which is similar to Stone's Strongly Implicit Method but free from parameters requiring case-to-case adjustment and so less complex and slower. The pressurecorrection equation is solved in a 'whole-field' manner, 2-D simultaneous. Further details may be found in refs. $[16,17]$.

### 3.3. The Nusseit number

From the engineering viewpoint, the most important characteristic of the flow is the rate of heat transfer across the cavity. The Nusselt number on the hot wall at $y=0$ is given by

$$
\begin{gather*}
N u(=)=\left(\frac{\bar{c} \theta}{\bar{c} \bar{y}}\right)_{T=0}=\left(\frac{\partial T}{\partial y}\right)_{T=0} \frac{D}{T_{H}-T_{\mathrm{C}}} ;  \tag{8}\\
\left(\frac{\bar{c} T}{\bar{c} y}\right)_{Y=0}=\frac{\dot{q}_{w o l l}^{\prime \prime}}{\kappa} ;  \tag{9}\\
N u(=)=\frac{\dot{q}_{m \mathrm{man}}^{\prime \prime \prime}}{\kappa} \frac{D}{T_{\mathrm{H}}-T_{\mathrm{C}}} ; \tag{10}
\end{gather*}
$$

where the heat flux at the wall. $\dot{q}_{\text {and }}^{*}$, is calculated by the program. from wall-functions [12, 19].

The average Nusselt number is given by

$$
\begin{equation*}
\overline{N u}=\int_{0}^{1}\left(\frac{\bar{c} \theta}{\bar{c} \bar{y}}\right) \mathrm{d}=\left.\right|_{\bar{j}=0 \text { or } 1} \simeq \frac{1}{N} \sum_{j=1}^{N} \frac{\hat{c} \theta}{\hat{\partial} \bar{y}}\left(0, \bar{z}_{j}\right) . \tag{11}
\end{equation*}
$$

The mid-plane value $N u_{1}$ : is also computed as it is probably [3] a more accurate quantity in describing the hear flow across a cavity with adiabatic end' wails. The three- and five-point formulae commonly used by other investigators [20] for resolving the wall temperature gradient in equation (8) were also used. The five-point
formula gave results very close to the ones calculated by equation (10) for Ra up to $10^{8}$, but it became erroneous, as expected, for the high Ra numbers.

## 4. RESLLTS A.ND DISCUSSION

The main results are presented in graphical and tabular form. and as $N u$ vs $R a$ correlations. The graphical resuits are obtained by the post-processor GRAFFIC [21].
Solutions were computed for $\operatorname{Pr}=0.71$ (air) and Ra between $10^{3}$ and $10^{10}$. The solutions for $R a$ up to $10^{6}$ were obtained by using normalized variabies. in such a way that dimensionless velocities were of the order of unity, in order to improve the numerical accuracy of the results. Indeed it was found that this procedure led to a $3 \%$ improvement in the important parameters over the dimensional solution, due to the limited accuracy of the mini-computer used.
The validity of the relationship $\theta(y, z)=\theta(1-y$, $1-3$ ), where 0 is the dependent variable was found to hold for all the solutions obtained, with very close approximation, everywhere in the flow field. An exception to this was in the cavity core for $R a>10^{12}$, probably due to the round-off error in the very small velocities encountered in this region. as compared with the large ones at the wall boundary layers; but even then the departure from the above centro-symmerry was within a few percent.

The presented results are practically grid independent (see Section 6 on grid dependence).
The velocity components at the domain centre-lines are shown in non-dimensional form (using $\kappa / D$ as a scale factor, where $\kappa$ is the thermal difusivity) in Figs. 24. for Rayleigh numbers $R a=10^{3}, 10^{5}$ and $10^{6}$.

It can be seen irom these graphs that as the Rayleigh number increases. the velocity maximum moves closer to the wall and its amplitude increases. At the same time. the velocity between the two maxima becomes progressively smailer and at $R a>10^{6}$ flow reversal is observed immediately outside the boundary layers. The reason for the above behaviour will be explained in conjunction with the thermal distribution inside the section.
Figure 5 shows streamlines for $R a=10^{3}-10^{16}$. Corresponding maps of temperature are shown in Fig. 6. The presented contours, in all the figures are labeiled according to a well-known convention. For example. in Fig. 6 the contours are labelled via the statement $283(2) 303 \mathrm{~K}$. This means that temperature contours are presented every 2 K with the first (at the extreme right) corresponding to 283 K and the last to 303 K.
At $R a=10^{3}$. streamlines are those of a single vortex, with its centre in the centre of the domain. Corresponding isotherms are paraliel to the heated walls. indicating that most of the heat transfer is by heat conduction. The effect of convection is seen as the departure of the isotherms from the vertical. The vortex is generated by the horizontal temperature gradient

Fic. 2 (a) The vertical velocity componeat: $R a=10^{3}$. (b) The horizontal velocity component: $R a=10^{3}$.

Fic. 3. (a) The verical velocity component: $R a=10^{5}$. (b) The horizontal velocity component: $R a=10^{5}$.

Fic. 4. (a) The verrical velocity component: $R a=10^{6}$. (b) The horizontal velocity component: $R a=10^{6}$.
across the section. This gradient, $\partial T / \partial y$, is negative everywhere in this case, giving rise to positive (clockwise rotation) vorticity.
As the Rayleigh number increases ( $R a=10^{4}$ ) the central streamline is distorted into an eliptic shape and the effect of cenvection is more pronounced in the isotherms. Temperature gradients arenow moresevere near the vertical walls, but diminish in the centre This behaviour continues to $\mathrm{Ra}=10^{5}$; the central streamline is further elongated and two secondary vortices appear inside it Its long axis is now tilted in the direction of the flow, as the secondary vortices are convected by the flow in the periphery. Heat transfer by convection in the viscous boundary layers alters the temperature distribution to such an extent that temperature gradients in the centre are close to zero. or change sign, thus promoting negative vorticity. This causes the development of secondary vortices in the core.

As discussed in ref. [22], the secondary vortices in the square cavity do not result from an instability of the base flow but are a direct consequence of the convective distortion of the temperature field. As Raincreases, the development of thermal boundary layers intensifies $\bar{\sigma} / \bar{\sigma} y$ in the vicinity of the walls, and the convection within each layer leads to negative $\partial T / \overline{\partial y}$ in the centre. A vorticity sink thus separates the regions of concentrated vorticity generation and two secondary
vortices are formed. Viscous diffusion appears to prohibit the development of these vortices for Ra $<10^{5}$. The vortices at $R a=10^{5}$ are sufficiently strong to convect the temperature fields to the extent that the isotherms are neariy horizontal in the centre, preventing any vertical motion there (see w-velocity plots in Fig. 3).
Increasing Ra to $10^{6}$, causes the secondary vortices to move closer towards the walls and are convected further downstream. A third vortex appears in the centre of the section, again rotating clockwise. This is surprising, as one would expect this last vortex to rotate counterclockwise, to reduce the shear between the other two vortices. Mallinson and de Vahl Davis [22] attribute this to the presence of a small positive temperature gradient in the centre. Viscous diffusion between the secondary vortices dissipates any counterclockwise vortices that might appear. Heat transfer is now mostly by convection in the rapidly moving fluid near the wails. The boundary layers adjacent to the vertical walls have become thin and fast. In the central region the vertical stratification in the temperature distribution. shown in Fig. 6 with increasing values from the bottom to the top of the cavity, prevents any vertical motion as confirmed by the w-plots in Fig. 4. In general. as $R a$ is increased $w$ tends to become comparatively small outside the vertical boundary layers, and is virtually zero over the central

 ( g$) R a=10^{12} ;(\mathrm{h}) R a=10^{16}$.

(h)

Fic. 6. Isotherms: (a) $R a=10^{3}$; (b) $R a=10^{6}$; (c) $R a=10^{5}$; (d) $R a=10^{4}$; (c) $R a=10^{\mathrm{A}}$; ( $\cap$ ) $R a=10^{10}$; (g) $R a=10^{12} ; R a=10^{\circ 6}$. Contours at $283(2) 303 \mathrm{~K}$, except ( f ) which is at $288(1) 298 \mathrm{~K}$.
$60 \%$ of the cavity width at $R a=10^{\circ}$. The maximum and minimum $w$ values for each profile are strongly affected by the Ra number as shown in Table 1. In chis tabie fand also in Table 2) the velocities are normalized using $D$ as a scale factor for length and $D^{2}, k$ as a scale factor for time. The results obtained for $R a=10^{6}$ were identical whether the $(k \sim \varepsilon)$ model was used or not, due to virtually zero $k$ generation.

As the Ralyeigh number increases from $10^{6}$ to $10^{8}$. the secondary vortices generated in the central core. are convected further upstream and closer to the differentially heated wails. The central vortex has now diffused into the other two vortices which become a dominant feature of the flow. The boundary lavers on the heated walls are now very thin. At the upstream corner of each boundary layer. the low momentum outer layer is absorbed by the adjacent vortex, while the rest of the boundary layer follows the adiabatic wall under the action of the secondary vortices.

For $R a=10^{10}$ the central vortex reappears [Fig. $5(\mathrm{f})]$ and the other two vortices are shifted closer to the wails and get thinner and elongated. As Ra increases further, the vortex system becomes progressively weaker and eventually ( $R a=10^{16}$ ) disappears compietely. High velocities now only occur within the thin boundary layers. and the flow in the central core is stratified. The streamine patterns of Fig. $5(\mathrm{~h})$ show this fenrure very clearly. Recirculation now only exists within the isothermal layers of fluid and the sense of rotation alternates berween adjacent layers.

The accompanying temperature maps, for $R a=10^{8}$ and $10^{10}$ show the temperature range in the core diminishing, from between 289 and 297 K to 291 and 295 K . A steep temperature gradient accompanies the location of the secondary vortices. The horizontal extent and magnitude of this gradient determines the extent and strength of the vortices described earlier. The negative temperature gradient in the central vortex is observed. For high Ra. the $T$-profiles bave a very steep slope within the thermal boundary layers; and this becomes steeper as $R a$ increases. Outside the boundary layers the $T$-profiles are almost horizontal and temperature increases with $=$.

Surprisingly, as the Rayleigh number increases even further. the temperature range in the core increases again. to between 288 and $298 \mathrm{~K}\left(\mathrm{Ra}=10^{12}\right)$ and finally to 287 and 299 K at $R u=10^{16}$. This is due to weak interchange of heat and momentum between adjacent fluid layers as the flow becomes increasingly stratified. At the same time. the temperature gradient in the horizontal direction diminishes to zero. This is to be expected. since now the walls are 'too far away' to have any influence in the core ( $R a \propto D^{3}$, while $\left.\delta x D^{-3 \cdot 4}\right)$.

Figures 7 and $S$ show horizontal and vertical veiocity contours at various Ra numbers. For Rayleigh numbers up to $10^{\circ}$ these contours are normalized. but not for the higher ones. The main observations discussed so far can also be inferred from these figures. i.e. the location and thickness of the boundary layers and the location of reverse flow regions accompanying

Note: (1) Present solution: (2) de Vahl Davis' solution [3].
the secondary vortices. The vertical velocity maximum moves closer to the hor wall as the Rayleigh number increases. and it is close to the centre of the hot wall for Rayleigh numbers up to $10^{6}$ (see also Table 1). The maximum horizontal component also moves closer to the hot wall as the Rayleigh number increases, and is shifted upwards.
Figure 9 shows the resulting velocity fields. The boundary layer profiles and the diminishing velocity field in the centre are clearly seen. An eniarged view of the central portion of Fig. 9(d) (indicated by the dotted line) shows cleariy the presence and direction of the three secondary vortices (Fig. 10).
Figure 11 presents boundary layer velocity profiles at the 'hot' wall for $R a=10^{12}$. at various $E$-locations. The boundary laver gets progressively thicker as we move from the bottom ( $I Z=15, \equiv=0.0075$ ) up to $z=0.5$. Further up, $z=0.795$. negative fiow is observed at the edge of the boundary layer, which is now thinner. The reason for this was explained earlier in connection with the presence of the secondary vortices. The boundary layer at $\equiv=0.9925$ has almost disappeared as it approaches separation at the top corner. Inspection of the derailed results indicates that both velocity components are indeed negative at that comer. The velocity profiles within the boundary layers are not
logarithmic in nature (neglecting the near-wall points where a logarithmic profile was imposed by the use of the 'wall functions'). This is in agreement with the results of George and Capp [27].
Figure 12 presents w-velocity profiles within the narrow boundary layer near to the hot wall, for $R a$ $=10^{10}$ with two different scaling factors. Three profiles are presented at three borizontal stations, $z / D=0.25$, 0.50 and 0.75 . Figure 13 presents the same information for $R a=10^{12}$.

The important quantiies for the problem considered, e.g the Nusselt numbers and the maximum velocities are summarized in Table 1. The table shows the calcuiated Nusseit numbers at the 'hot' wall.
The maximum and minimum values are given in the table, together with the Nusselt number at $\bar{y}=y / D$ $=0.5$. The same table, contains values of the maximum vertical velociry component on the horizontal mid-line and its location, the maximum horizontal veiociry on the vertical mid-line and its location and the maximum horizontal and vercical velocities over the whole domain and their location.
The heat transfer coefficient is seen to increase with Rayleigh number, as convection becomes dominant, but not as fast as the flow. Thus, passing from $R a=10^{3}$ to $10^{6}$ leads to an increase of $w_{\max }$ from 3.59 to 221.8:

but the maximum Nusseit number increases only from 1.496 to 17.87 , despite the passage from diffusiondominated to convection-dominated transfer, as revealed by the configuration of the isotherms.
The maximum Nusselt number occurs at the bottom of the cavity and the minimum at the top.
The results for Rayleigh numbers up to $10^{6}$ are compared with the benchmark solution provided in ref. [3] which can be considered as accurate. The qualitative agreement of the presented piots of stream function. temperature and velocity maps with those of the benchmark solution is very good. Quantitative
comparison is provided by the Nusselt numbers and the maximum velocity values in Table 2 Agreement is generally good. Differences exist in the minimum Nusseit number, particularly at $R a=10^{\circ}$. Although the agreement of the maximum and centre-line Nusselt numbers is better than $1.5 \%$ over the whole $R a$ range. the present predictions indicate a higher minimum Nusselt number than the benchmark solution.

Numerical errors and the first-order differencing scheme used in this work do not account for the observed differences, since the results are practically grid independent. However, there are two other

differences between the procedures, namely the elimination of the Boussinesq assumption in the present work and the implied use of the linear velocity profile berween wall and near-wall points, in the shearstress calculation. The latter shouid not account for any diference either, provided that the benchmark solution has properiy computed the wall shear-stresses.
The computations were repeated by using the Boussinesq approximation. Minor differences were observed for $R a=10^{3}$ and $10^{4}$, with a maximum of $1 \%$. For $R a=10^{5}$ and $10^{6}$ the differences were up to $3.7 \%$; the minimum Nusselt number being 0.804 at $R a=10^{5}$ and 1.188 at $R a=10^{\circ}$. The large errors in the calculation of the minimum Nusselt number appear to be due to the sensitivity of its calculation. Suppose for

Fig. 12 w-Velocity profiles within boundary layer, $R a=10^{10}$ (two scaling factors). Three horizontal stations at: (1) $=/ \mathrm{D}$
$=0.25:(2)=D=0.50:(3) \div D=0.75$.
example that at $R a=10^{6}$ the solution predicts a nearwall maximum temperature of 302.81 K instead of the correct value of, say, 302.84 K . This represents a very accurate temperature prediction with an error of less than $0.01 \%$ (well within the convergence criterion used, see Section 5). For a wall temperature of 303 K , the application of a one-sided formula for calculating a temperature gradient at the wall, would lead to a $N u_{\text {min }}$ which for the present grid spacing would be 1.267 instead of 1.067 , e.g. in error by $19 \%$. The same is not true in the case of $N u_{\text {max }}$. Thus the same accuracy in temperature (say 300.43 K instead of 300.4 K ) leads to $N u_{\text {max }}=17.13$ instead of 17.33 . e.g. in error by only $1 \%$ Therefore, despite the large errors at $R a=10^{6}$ in the derived quantities, it is suggested that the present

Fic. 13. w-Velocity profiles within boundary layer, $R a=10^{12}$ (two scaling factorsh) Three horizontal stations at: (1) $=1 D$ $=0.35:(2)=i D=0.50:(3) z / D=0.75$.
solution may still be about $1 \% \%$ accurate in terms of the computed primitive variables.

Direct comparisons are not possible for the turbulence runs, due to the scarcity of experimental evidence. However, the use of the $k \sim \varepsilon$ model in other related work (e.g. buoyant turbulent flow in buildings) has led to favourable comparisons with experiment [15].
Furthermore, the presented solutions certainly show some of the features that are observed experimentally (position of vortices and their shifting with increasing $R a$ number. thermal stratification, ete.) and indicate, qualitatively at least, the correct change in flow structure as $R a$ increases.
Finally; the correlations of the present results given beiow are in good agreement with well-known correlations derived from a large number of experiments for Ra up to $10^{a}$ [23], and appear to extend the validity of those correlations up to $\mathrm{Ra}=10^{12}$. For higher $R a$ a set of new correlations is proposed.

### 4.1. Derited $N u \sim R a$ correlations

The following correlations for maximum, minimum and average Nusselt numbers were derived from the present predictions by least-square linear regression.

Laminar $\left(10^{3} \leqslant R a \leqslant 10^{6}\right)$

$$
\begin{gather*}
N u_{1 ; 2}=\overline{N u}=0.143 R a^{0.399} ;  \tag{12}\\
N u_{\max }=0.130 R a^{0.356} . \tag{13}
\end{gather*}
$$

The minimum $V u$ is not given as the $\log N u$ vs $\log R a$ curve is not a straight line.
Turioulent ( $10^{6}<R a \leqslant 10^{12}$ )

$$
\begin{align*}
& \overline{N u}=0.082 R a^{0.329} ;  \tag{14}\\
& N u_{\max }=0.057 R a^{0.3 \div 9}:  \tag{15}\\
& N u_{\min }=0.016 R a^{0.315} \tag{16}
\end{align*}
$$

$$
\text { Turbuient }\left(10^{12}<R a \leqslant 10^{16}\right)
$$

$$
\begin{equation*}
\overline{N u}=1.325 R a^{0.245} \tag{17}
\end{equation*}
$$

$$
\begin{equation*}
N u_{\max }=0.34 R a^{0.316} \tag{18}
\end{equation*}
$$

$$
\begin{equation*}
N u_{\text {min }}=0.137 R a^{0.233} \tag{19}
\end{equation*}
$$

### 4.2 Comparison with experimental correlations

The above correlations are compared with the following experimental ones in Table 3 [23]:
laminar
$\overline{N u}=0.196 R a^{1+4}\left(\frac{L}{D}\right)^{-19}$

$$
\begin{equation*}
\left(2.8 \times 10^{3}<R a<28 \times 10^{4}\right) ; \tag{20}
\end{equation*}
$$

turbulent
$\bar{\nabla} u=0.072 R a^{1.3}\left(\frac{L}{D}\right)^{-19}$

$$
\begin{equation*}
\left(2.8 \times 10^{+} \leqslant R a \leqslant 1.55 \times 10^{7}\right) ; \tag{21}
\end{equation*}
$$

where $L D$ is the cavity aspect ratio.

It can be seen that extrapolation of the experimental turbulence correlation up to Rayleigh numbers of $10^{12}$ is in good agreement with the present predictions. despite the fact that the former is applicable to cavities of aspect ratios between 3 and 42 The aspect-ratio eifect explains the relatively large diferences observed for the lower Ra numbers, and the closer agreement obtained for higher Ra numbers: the effect of aspect ratio diminishes as $R a$ increases.

The switch in the exponent of the Rayleigh number for the correlations for $R a>10^{12}$ was introduced simply by requiring a zero error from the lenst-square linear regression. Experimental evidence. however limited. indicates an exponent of $1 / 3$. If the exponent of $R a$ is assumed to be $1 / 3$, then the best correlation of the present results over the whole of the turbulent range gives

$$
\begin{equation*}
\overline{N u}=0.060 R a^{1 / 3} \tag{22}
\end{equation*}
$$

The above correlation gives higher values than those obrained by MacGregor and Emery ( $\overline{N u}=0.046 \mathrm{Ra}^{1 / 3}$ ) [28] and by Cowan et al. ( $\overline{N u}=0.043 \mathrm{Ra}^{1 / 3}$ ) [26]. However, the former [28] refers to cavities of aspect ratio $10-40$ with constant heat flux boundary conditions at the hot face, and isothermal coid face and the latter [26] refers to water and to Ra numbers up to 2 $\times 10^{11}$.

## 5. CONVERGENCE AND COMPLTER TIME

A converged solution was defined as one that met the following criterion for ail dependent variables

$$
\max \left|\phi^{n+1}-\phi^{n}\right| \leqslant 10^{-4},
$$

between sweeps $n$ and $n+1$. At this stage mass continuity errors per slab were of the order of $10^{-3}$ and therefore insignificant. Further sweeps of the solution domain confirmed no changes and were actually pointless since the accuracy limit of the computer was approached. The sum of the absolute volumerric error over the whole field was again insignificant. at $10^{-6}$.

Convergence was lound to be affected by the Rayleigh number. Hence the high Rayleigh number cases required more sweeps than the low ones. To improve convergence a false time-step relaxation was used. This was reduced by an order of magnitude. from 0.1 to 0.01 for both velocities. for $R a>10^{\circ}$. and to 0.001 for $\mathrm{Ra}>10^{10}$. This is to be expected since this relaxation factor is proportional to the fluid residence time in a typical cell: and it is therefore appropriate to reduce it as the velociry in the boundary layers increases with Rayleigh number.

To economize on run-times each Rayleigh number case was restarted from the previous one (starting with $R a=10^{3}$ ) and 200 sweeps were found adequate for convergence. The domain dimension $D$ was the parameter adjusted to get the required Rayleigh number value.

Fig. 14. Velociry comparison ( $R a=10^{6}$ ) for $40 \times 40$ and $80 \times 80$ solutions.

A 100 -sweep run required 11 min CPU time on the Perkin-Elmer 3220 mini-computer, for the 30 $\times 30$ grid. and 15 min for $\mathrm{a} 40 \times 40$ grid. The above minicompurer is several times slower than mainframe machines. In general, the time per finite-domain cell, per sweep, per variable was $1.5 \times 10^{-3} \mathrm{~s}$ CPU on the Perkin-Elmer machine. A full run at $R a=10^{14}$ using a $60 \times 60$ grid would require 300 sweeps and take 25 h on the mini-computer for solving the six equations (c. w, p. k.e. T).

It is not an easy matter to compare the above reported CPU times with those of other methods in the literature, because of different computers used and different practices in reporting these cimes.

However, it appears to the authors after their survey that the present computer-time requirements are modest. and possibly an order of magnitude less than those reported in the literature for the same cases. If true, this is certainly due to the speed of the SIMPLEST algorithm and the associated whole-field pressure solver, coupled with the thorough opamization of FORTRAN arithmetic and the very orderly bookkeeping in the software, embodying the solution procedure.

## 6. GRID DEPENDENCE AND COMPUTER STORAGE

Iniual investigations were performed on a uniform $30 \times 30$ grid. This was found to be adequate for $R a$ $=10^{3}$. but not for higher values. An improved $30 \times 30$ grid was then used, with closer spacing near the walls (Fig. 1), to increase boundary layer resolution.

This grid was used for all Rayleigh number cases up to $R a=10^{\circ}$ and the results were stored.
To check grid dependency, the grid was further refined to $40 \times 40$ by adding intermediate cells in the central region. All cases (up to $R a=10^{\circ}$ ) were re-run restarting from interpolation of the $30 \times 30$ results, for another 100 sweeps. In their bulk. the results showed little change. although the secondary vortices at $R a$ $=10^{5}$ and $10^{6}$ were, as expected, better resolved. The maximum velocity increased by $5 \%$ in the $R a=10^{5}$ case. and these are the results presented in this paper.

The grid was refined again to $80 \times 80$ by haiving all cells and the $R a=10^{6}$ case was run for another 300 sweeps. Very minor changes were observed, as shown in Fig. 14, for the velocity profile inside the hot wall boundary layer. The maximum velocity increased by $0.4 \%$ in the $R a=10^{6}$ case. The same observations apply also to the temperature-field changes with grid refinement. It is concluded that the results up to Ra $=10^{6}$ are pracrically grid-independent.
For the turbulent cases care was taken to place 10-15 grid ceils inside the wail boundary layers. The thickness of these layers is given by $\delta / D=4.86 \mathrm{Ra}^{-1 / 4}$ for Pr $=0.71$. Care was also taken to concentrate several of these $10-15$ points berween the velocity peaks and the wall, and to place the first grid point very close to the wall $y / D=1 \times 10^{-6}$ for the high $R a$ numbers, $y^{-}$ varying berween 1 and 12 along the hot wall). The above considerations are very important for treating the boundary layers in accordance with the essential physics, since in the wall region temperature gradients are most severe and hence provide an important source of vorticity. If the first grid point is too far from the wall then the results will be grossiy distorted by this effect. Three grids were used, $\left({ }_{0},=3\right)=40 \times 80,60 \times 120$ and 100 $\times 160$. Practically grid-independent results seemed to be obtained using a grid of $(y, z)=60 \times 120$ for all $R a \geqslant 10^{8}$; the $100 \times 160$ grid leading to a maximum further change of $1.2 \%$ for the maximum velocities and $1.5 \%$ [or temperature. For $R a>10^{14}$ the resulting grid cells in the core were thought to be too ill-conditioned (aspect ratio of up to $10: 1$ ) for sufficient accuracy. However, the flow in the core for these high Ra numbers is nearly stagnant and the cell aspect-ratio effect appears not to be important, as was indicated by repeating the runs with halr the above ratios.

The program required 90 K -words; of these. 35 K words were required for data storage ( $30 \times 30$ grid).

## 7. CONCLUSIONS

The probiem considered represents a 2-D approximation to a series of practical probiems. The study
demonstrated that numerical solutions can be obtained quickiy and economically for such problems，where buoyancy effects are dominant．

Accurate results were obtained at both ends of the Rayleigh number scale．at least for the laminar range． indicating that both difiusion－oniy or convection－only heat transfer problems can be tackled with ease．The results were presented in graphical and tabuiar form． and as correlations between the Nusselt and Rayleigh numbers．

The main points of the present method can be summarized as follows：（a）the model consists of the coupled differential elliptic equations which are solved over the entire flow domain，with no assumption concerning the core configuration：（b）the procedure is strongiy convergent and results were easily obtained even at Rayleigh numbers as high as $10^{16}:(\mathrm{c})$ practically grid independent results were obtained with only modest computer storage and CPU time requirements． Indeed．a survey revealed that the present method may be up to an order of magnitude faster than ocher available procedures．enabling very fine grid runs to be performed within practicable resources：（d）the procedure and associated computer program are general and can be used immediately for 3－D narural convection probiems in cavities of any aspect ratio and orientation．and fluids of any Prandtl number．It is therefore immediarely applicable to all related practical probiems：（et the speculative use of the $(k \sim \varepsilon)$ model in this work has indicated that despite its well－known deficiencies in terms of physical realism．it may still lead to a reasonable prediction of the overall fow structure of the problems considered；（f）apart from the uncertainty connected with the $(k \sim \varepsilon)$ model itself another source of uncertainty is provided by the＇wall－ functions＇．More work is required to establish more realistic＇wall－functions＇for buoyance－dominated flows．Once established．it is a ver：simple matter to incorporate in the present model．

Although oniv time－averaged steady－state results have been presented．the procedure can also be used in its in－built transient mode．Also radiation and variable property effects．that have been negiected in the present study，must be included to investigate their im－ portance at high Rayleigh numbers．Finally，much more experimental work is required for high Ra numbers to provide data for improving and validating the computer models．

## APPENDIX

## THE WALL BOUNDARY CONDITIONS

The treatment of wall boundary conditions for turbuient buoyant flows presents a source of uncertainty in the present work. It is therefore worthwhile describing briefly what was done. 'Wall functions' were used for both the laminar and turbulent calculations. In the laminar cases this simply meant that the wall shear stress was evaluated from the presumption of a linear velocity variation between the calculated near-wail value and the zero wall value.
The shear stress calculated in this way was then included as a source term for the velocity component parallel to the wail. For the turbulent calculations. the Reynolds aumber for the near-wall point was first evaluated. If this was less than 132.25 $v^{-}=11.5$, the value ar which the laminar and turbulent wall-
functions intersect) the above laminar wall-function was also used. If the Revnolds number was greater than 13225. the presumed velocity variation was logarithmic and the corresponding shear-stress coefficient was evaluated. Both $k$ and $c$ were fixed at the near-wall grid nodes at the values which would prevail there if indeed the universal logarithmic veiocity profile prevailed. The wall heat transfer rate was evaluated from the Chilton-Colburn form of the Reynolds analogy, in which the Stanton number ( $S O$ ) is related to the friction coefficient $\left(C_{1}\right)$ as follows:

$$
\begin{equation*}
S t=C_{1} P r^{-2: 3} \tag{A1}
\end{equation*}
$$

where $C_{f}$ is related to the wall shear stress ( $\tau_{w}$ ) and the parallel-to-wall velocity $|w|$ as follows:

$$
\begin{equation*}
C_{f}=\tau_{-\infty}\left(\rho|w|^{2}\right) . \tag{A2}
\end{equation*}
$$

The heat transfer rate per unit area at the wall $\left(\dot{q}^{\prime \prime}\right)$ is then deduced from:

$$
\begin{equation*}
\dot{q}_{w}^{\prime \prime}=S t \rho|w| C_{p}\left(T_{p}-T_{w}\right) \tag{A3}
\end{equation*}
$$

where $T_{p}$ is the temperature at the grid node in question, and $T_{w}$ the temperature at the wail.

It is realized that the wail functions may be influenced considerably by temperature variations, and indeed that the logarithmic form used is probably not appropriate since buoyancy effects are ignored in the log layer. A better wail function couid be based on either the Monin-Obukov loglinear profile [29], or on the cube root profiles of George and Capp [27].

CONVECTION LAMINAIRE ET TURBULENTE DANS UNE CAVITE FERMEE

Résumé-On présente une méthodenumérique pour obtenir des solutions d'écoulement narurel et de transfert de chaieur dans une cavite carree avec des parois latérales chauffées diffëremment. On étudie un domaine de nombres de Rayleigh entre $10^{3}$ et $10^{\circ}$. On utilise une differenciation de cellules donatrices et des études de maillage sont développees pour tous les nombres de Rayieigh considéres. Le modèle de turbulence utilisé pour les nombres de-Rayleigh supérieurs à $10^{\circ}$ est un modèle ( $k-8$ ) à deux équations qui inclut les interactions gravite-gradient de masse volumique. Les résultats sont présentés sous forme de tables et de graphiques et de formules de nombres de Nusselt et de Rayleigh. En outre. les résuitats de nombres de Rayieigh jusquä $10^{6}$ sont comparés avec la solution numérique de Vahl Davis.

## LA:MINARE UND TURBULENTE FREIE KONVEKTION IN EINEM GESCHLOSSENEN HOHLRAUM

Zusammenfassung-Es wird eine Berechnungsmethode beschrieben. die dazu dient. Lōsungen für die laminare und turbulente, von Auftriebskräften bestimmte Strömung und den Wärmeübergang in einem Hohlraum mit quadratischem Querschnitt und unterschiedlich beheizten Seitenwänden zu erhalten. Die Rayleigh-Zahi wurde im Bereich von $10^{3}$ bis $10^{\circ}$ variiert. Es werden "donor-cell"-Differenzen verwendet. Einflüsse der Gitterverieinerung wurden bei ailen betrachteten Rayieigh-Zahien untersucht. Ais Turbulenzmodell für Ravieigh-Zahien größer $10^{\circ}$ wurde ein $1 k \sim \varepsilon$-Modell verwendeL, welches Wechseiwirkungen zwischen Schwerkraft und Dichtegradienten berücksichtigl. Die Ergebnisse werden in tubellarischer und grafischer Form und ais Korretationen von Nusselt- und Rayleigh-Zahlen dargestell. Die Ergebnisse für Rayieigh-Zihhlen bis $10^{\circ}$ werden mit den Referenz-Lösungen von de Vahl Davis verglichen.

## ЛАМИНАРНАЯ И ТУРБУЛЕНТНАЯ ЕСТЕСТВЕННАЯ КОНВЕКЦИЯ В ЗАМКНУТОЙ ПОЛОСТИ

#### Abstract

Анноташв-Описывается численный метод решения задач свободноконвективного ламинарного и турбулентного течения и теплопереноса в квадратной полости с о́оковыми стенками. нагретыми по разной температуры. Иселедования проволились в папазоне эначений чиста Релея от $10^{3}$ до $10^{16}$. При построении разностной схемы ислользованы донорские ячейки. Дาя всех рассматриваемых значений числа Релея провопились нсстедования влияния измельчения сетки на решение. При значениях числа Релея. превышаюших $10^{\circ}$. использовалась двухпараметрическая ( $k \sim \varepsilon$ ) модель турбулентности, учитываюшая взаимодействие между силой тяжести и градиентом плотности. Результаты представлены в випе таб̈.тиц и тафиков. а также в виде обоб́шенных зависимостей между числами Нуссепьта п Релея. Кроме того. проведено сравнение результатов, полученньх при числах Релея, меньших $10^{\circ}$, с численным решением де Вааль Дависа.
